

**Emigration of Juvenile Chinook Salmon (*Oncorhynchus tshawytscha*) and
Steelhead (*Oncorhynchus mykiss*) in the Lower Mokelumne River,
December 2009 through July 2010**

Robyn Bilski, Jason Shillam, Charles Hunter, Matt Saldate and Ed Rible
East Bay Municipal Utility District, 1 Winemasters Way, Unit K, Lodi, CA

Key Words: chinook salmon, emigration, juvenile monitoring, lower Mokelumne River, steelhead

SUMMARY

The emigration of juvenile chinook salmon (*Oncorhynchus tshawytscha*) and steelhead (*Oncorhynchus mykiss*) on the lower Mokelumne River was monitored using two rotary screw traps (RST) and a bypass trap during the 2009/2010 season. The upstream rotary screw trap (VINO) was positioned just upstream of the Elliot Road bridge at river kilometer (Rkm) 87.4 and was operated from 30 November 2009 to 9 July 2010. The downstream rotary screw trap (GOLF) was located just below the Lower Sacramento Road Bridge at Rkm 61.8 and was operated from 14 December 2009 to 14 July 2010. The smolt bypass trap was located at Woodbridge Irrigation District Dam (Rkm 62.2) and was operated from 7 April 2010 to 16 July 2010.

The first juvenile chinook salmon was captured at the VINO RST on 18 December 2009. Fourteen trap efficiency tests were conducted at VINO during the monitoring period. Trap efficiencies using wild salmon as test fish were significantly higher than trap efficiencies using hatchery salmon as test fish. Consequently, eight trap efficiency trials were used to generate the chinook salmon abundance estimate, seven using naturally produced salmon and one using hatchery produced salmon. The total estimated abundance of naturally produced juvenile chinook salmon passing the VINO site during the monitoring period was 124,279 (95% CI: 93,555-199,950). Twenty-four wild age 0+ steelhead were caught at VINO between 25 February and 2 July 2010. Estimated passage of wild age 0+ steelhead (based on trap calibrations using salmon) was 745 (95% CI: 507-1,406).

At the downstream RST (GOLF), the first juvenile chinook salmon was captured on 5 January 2010. Eight trap efficiency tests using hatchery produced salmon were conducted at GOLF during the monitoring period. Trap efficiencies ranged from 0.3% to 4.4% and averaged 1.9%. The total estimated abundance of naturally produced juvenile chinook salmon passing the GOLF site was 66,751 (95% CI: 38,914-283,316). Thirty-five wild age 0+ steelhead were captured at GOLF between 22 April and 14 July 2010. Based on trap efficiencies using salmon, the estimated abundance of wild age 0+ steelhead passing the GOLF RST was 6,955 (95% CI: 4,344-20,897).

A total of 397 naturally produced chinook salmon were caught at the smolt bypass trap (BYPASS). Estimates for weekend catch were added to actual catch to produce an

estimated count of 598. The total downstream salmon emigration estimate, calculated from adding the BYPASS trap and the GOLF RST estimates, was 67,349 (95% CI: 39,512-283,914). Ninety wild age 0+ steelhead were caught at the BYPASS trap during the season. Estimates for weekend catch were added to actual catch to produce an estimated count of 149 age 0+ wild steelhead.

Nineteen fish species were caught at the VINO RST during the survey period, 7 native and 12 non-native. Native fish species were more frequently caught than non-native species and chinook salmon were the most abundant species caught. At the downstream traps (GOLF and BYPASS) 28 fish species were caught, 8 native and 20 non-native. Native fish species were more frequently caught than non-native species and prickly sculpin (*Cottus asper*) were the most abundant species caught.

Water releases from Camanche Reservoir ranged from 329 cubic feet per second (cfs) (9.3 cubic meters per second (m³/s)) to 1,453 cfs (41.1 m³/s) during the monitoring period.

INTRODUCTION

East Bay Municipal Utility District (EBMUD) has been monitoring juvenile salmonid emigration on the lower Mokelumne River (LMR) since 1990 (Bianchi et al. 1992, Marine 2000). Nearly all salmonid spawning occurs in a 16 kilometer reach of the LMR below Camanche Dam (Setka 2004). Fish traps are operated with the objectives of estimating abundance and monitoring the emigration patterns of anadromous fish species in the LMR. This report presents the monitoring results for rotary screw trap and bypass trap operations from December 2009 through July 2010.

METHODS

Rotary screw traps

Two eight-foot diameter rotary screw traps (E.G. Solutions, Inc.) were operated at upstream and downstream locations on the lower Mokelumne River (Figure 1). The upstream RST was located near the Elliott Road Bridge, adjacent to property owned by VINO Farms, at Rkm 87.4. The downstream RST was located adjacent to the Lodi Golf and Country Club at Rkm 61.8, just downstream of Woodbridge Irrigation District Dam (WIDD). Both traps were operated at the same locations used during the previous two seasons (Pagliughi et al. 2008; Boyd 2009). In this report, the upstream and downstream RST sites are referred to as VINO and GOLF, respectively.

The traps were operated Monday through Friday, except between 13 April 2010 and 21 May 2010, when they were operated every day of the week. Rotary screw trap checks were performed once daily unless large flow fluctuations warranted a second debris check in effort to keep the traps rotating. During Monday through Friday operations, traps were taken out of service after each check on Friday afternoon. Traps were reset each Monday morning.

Efforts were made to maintain a rotational speed of two rotations per minute (RPM) or greater at both RSTs (USFWS 2008). Rotations were measured using a stopwatch to record the time for three full rotations. RPMs were taken at each trap check. Trap cables were adjusted to optimize rotations. Cone rotations since the previous trap check were read off of a Redington® mechanical counter mounted on side rails near the mouth of the cone. Water velocity was measured at the center of the trap cone, just below the water surface, at the beginning of each trap check. pontoons, cones, live boxes and decks were cleaned daily to maintain traps in good working order. Cables, pulleys, counters and cones were inspected daily to ensure proper function.

Bypass Trap

A smolt bypass trap was operated in the bypass pipe at WIDD (Rkm 62.2) during the 2009/10 trapping season. The bypass trap (referred to as BYPASS) conveys fish that are screened off of the Woodbridge Irrigation Canal when Woodbridge Irrigation District is diverting water from the LMR. The trap was checked once daily and was operated Monday through Friday, except between 13 April 2010 and 21 May 2010, when it was operated seven days per week. A fish crowder and a long-handled dip net were used to capture fish. Debris was cleared from the trap during each check. The bypass trap was also operated during the 2006/07 and 2008/09 monitoring seasons (Workman et. al. 2007; Boyd 2009).

Calibrations

Multiple trap efficiency tests were conducted at each RST throughout the outmigration period to provide an estimate of the proportion of juvenile chinook salmon each RST was capturing. Standard mark-recapture ratios were used as measurements of trap efficiency and calculated as follows:

$$TE = \frac{m}{M}, \text{ where}$$

TE = trap efficiency,

m = number of marked fish recaptured,

M = number of marked fish released.

Naturally produced chinook salmon were used for the trap efficiency trials when catch was high enough to produce a group of test fish. Additional test fish were provided by California Department of Fish and Game at the Mokelumne River Fish Installation (MRFI). Bismark® brown dye, upper caudal fin clips, and Visible Implant Elastomer (Northwest Marine Technology™) were used in different combinations to mark groups of test fish for the VINO trap. A lower caudal fin clip (sometimes in combination with Bismark® brown dye) was always used to mark test fish for the GOLF trap, providing the means to distinguish test fish between the two traps. The Bismark® brown dye was applied by holding test fish in an aerated tank of dye solution for approximately 60 minutes.

Mark retention and mortality rates were determined before releasing test fish. Calibration fish for GOLF were released below the face of Woodbridge Dam, approximately 0.1 km upstream of the trap location. Test fish for VINO were released approximately 0.25 km upstream of the trap location. The test fish were distributed proportionally to the flow across the river at each location.

Rotary Screw Trap Abundance Estimates

RST abundance estimates were generated for juvenile chinook salmon and steelhead using the Petersen equation (Volkhardt et al. 2007). Daily catch estimates were generated for non-trapping days by averaging daily catch for three days preceding and following these periods (Appendix A). Trap efficiencies were applied to daily catch estimates and daily catch numbers to produce daily abundance estimates:

$$DA = \frac{C}{TE}, \text{ where}$$

DA = daily abundance estimate,
 C = daily catch or daily catch estimate,
 TE = trap efficiency.

Annual abundance estimates were calculated by summing the daily abundance estimates. Ninety-five percent confidence intervals were calculated for each trap efficiency test using:

$$LCL = TE - 1.96\sqrt{TE \frac{(1-TE)}{M}}, \text{ and}$$

$$UCL = TE + 1.96\sqrt{TE \frac{(1-TE)}{M}}, \text{ where}$$

LCL = trap efficiency lower 95% confidence limit,
 UCL = trap efficiency upper 95% confidence limit,
 TE = trap efficiency,
 M = number of marked fish released,
 $TE \frac{(1-TE)}{M}$ = estimated variance of TE .

Daily confidence intervals for daily abundance estimates were calculated as follows:

$$DCI_{\text{low}} = \frac{C}{UCL}, \text{ and}$$

$$DCI_{\text{high}} = \frac{C}{LCL}, \text{ where}$$

DCI_{low} = daily abundance lower 95% confidence limit,
 DCI_{high} = daily abundance upper 95% confidence limit,

C = daily catch or daily catch estimate,
 UCL = trap efficiency upper 95% confidence limit,
 LCL = trap efficiency lower 95% confidence limit.

Confidence intervals for annual abundance estimates were calculated by summing the daily abundance confidence intervals.

BYPASS Trap Abundance Estimates

Daily catch estimates at the BYPASS trap were generated for non-trapping days by averaging daily catch to the nearest fish, for three days preceding and following these periods. Seasonal abundance was estimated by summing daily trap counts and daily estimates for non-trapping days over the monitoring period.

Fish Handling and Condition Factors

Captured fish were processed in the field, just adjacent to the trapping site, or in a tagging trailer near the trap. The trailer was equipped with a flow-through water supply and recirculating anesthetic bath to allow safe processing of larger numbers of fish. The trailer was used at VINO during the early season and later transferred to Woodbridge Dam to accommodate the processing of larger volumes fish at the GOLF and BYPASS traps. A 70 to 100 mg/L solution of tricaine methanesulfonate (MS-222) was used to anesthetize fish. Pumps and mechanical aerators were used to maintain suitable dissolved oxygen concentrations in all fish holding receptacles during processing.

During each trap check, up to 50 chinook salmon and up to 20 fish of other species from each trap were weighed and measured. Fish were weighed to the nearest 0.1 gram using an Ohaus® Scout portable scale. Fork lengths (FL) and total lengths (TL) of each fish were measured to the nearest millimeter (mm). Life stage and any observations of marks, injuries or anomalies were also recorded. Processed fish were allowed to recover before being transported to the release site by truck or boat. The fish were transported in 19 liter (5 gallon) buckets equipped with battery operated aerators and released approximately 0.4 kilometers (0.25 miles) downstream of the capture sites.

Fulton's Condition Factors (Bagenal and Tesh 1978) were calculated for up to 50 chinook salmon caught each trapping day:

$$K = \left(\frac{W}{FL^3} \right) * 100,000, \text{ where}$$

K = Fulton's Condition Factor,
 W = weight in grams,
 FL = fork length in mm.

Coded Wire Tagging

Mark IV tagging machines (Northwest Marine Technologies, Inc.) were used to implant half-length Coded Wire Tags (CWT) in juvenile chinook salmon caught in all traps.

Tagging was performed on trapped juvenile chinook salmon with total lengths ≥ 40 mm. Two numeric tag codes were used during the survey period. Standard coded wire tagging methods for juvenile salmon were followed (Vogel and Marine 1999).

Environmental Data

Turbidity samples were collected by submerging a sample jar to a depth of 0.3 m (1 ft) and allowing it to fill with water. Turbidity samples were processed in the lab using a Hach[®] P1000 turbidimeter. Water temperature and dissolved oxygen data were collected using a YSI 550A handheld dissolved oxygen meter. All water quality measurements were collected daily at each location when trap checks took place. Flow measurements were provided by EBMUD's Golf and Elliot Road gauging stations.

Data Analysis

Graphics production and data analyses were performed using ArcMAP, Arc/Info (ESRI) systems, JMPIN 4.0.4 (Academic), Microsoft (MS) Access 2003 and MS Excel 2003. A P-value ≤ 0.05 was considered statistically significant. Mean fork length was reported with ± 1 standard deviation (SD) for $n \geq 3$. Rotary screw trap abundance estimates were reported with 95% confidence intervals (CI).

RESULTS

Mokelumne River Flow, Temperature, Turbidity

Average daily flow at the Elliot Road gauging station (just below the VINO trapping site) ranged from 298 cfs (8.43 m³/s) to 1,464 cfs (41.43 m³/s), $x = 590$ cfs (16.7 m³/s) during the time the VINO trap was operated (30 November 2009 through 9 July 2010). Water temperatures recorded at the VINO trapping site were between 9.2 and 14.6°C, with an average of 11.6°C. Water turbidity in Nephelometric Turbidity Units (NTU) at the VINO RST ranged from 1.4 to 10.1 NTU with a mean of 2.4 NTU.

Average daily flow at the Golf gauging station ranged from 120 cfs (3.40 m³/s) to 1,248 cfs (35.32 m³/s), $x = 480$ cfs (13.59 m³/s) during the time the BYPASS trap was operated (7 April 2010 through 16 July 2010). Water temperatures recorded at the BYPASS trap were between 12.1 and 18.1°C, with an average of 15.1°C. Water turbidity at the BYPASS ranged from 1.8 to 4.2 NTU with a mean of 2.6 NTU.

Average daily flow at the Golf gauging station ranged from 120 cfs (3.40 m³/s) to 1,248 cfs (35.32 m³/s), $x = 480$ cfs (13.58 m³/s) during the time the GOLF RST was operated (14 December 2009 through 14 July 2010). Water temperatures recorded at the GOLF trapping site were between 8.6 and 17.5°C, with an average of 13.0°C. Water turbidity at GOLF ranged from 1.6 to 13.0 NTU with a mean of 3.2 NTU.

Average daily flow, water temperature and turbidity in the lower Mokelumne River are summarized at locations between Camanche Dam and the GOLF gauging station in Figure 2.

Trap Operations

The VINO RST was operated between 30 November 2009 and 9 July 2010. The cone was stopped by debris on 14 of 162 operating days. The minimum recorded cone rotation rate was 2.9 RPM and maximum was 5.1 RPM. Mean rotation rate during the monitoring season was 3.7 RPM. Excluding days with trap stoppages, the VINO trap met or exceeded the CAMP recommended minimum 2 RPMs (USFWS 2008) on 100% of all operating days. Water velocity entering the center of the trap cone ranged between 0.75 and 1.22 meters per second (m/s) and averaged 0.97 m/s.

The GOLF RST was operated between 14 December 2009 and 14 July 2010. Debris stopped the cone from rotating on 13 of 156 operating days. The minimum recorded cone rotation rate was 1.7 RPM and maximum was 4.7 RPM. Average rotational speed over the course of the monitoring period was 3.7 RPM. Excluding trap stoppages, the GOLF trap met or exceeded the CAMP recommended minimum rotation of 2 RPMs (USFWS 2008) on 99 % of all operating days. Water velocities entering the center of the trap cone ranged between 0.40 and 1.05 m/s and averaged 0.84 m/s.

The BYPASS trap at WIDD was operated between 7 April and 16 July 2010. During this time frame the trap was operated for 81 days. Water velocities at the top of the trap ranged between 0.74 and 1.01 m/s and averaged 0.89 m/s.

Calibrations

Fourteen calibration tests were conducted at the VINO RST during the 2009/10 trapping season (Table 1). Naturally produced chinook salmon were used as test fish for seven tests and MRFI salmon were used for seven tests. The final trap efficiency test (#14) was excluded because the trap was stopped by debris shortly after the test fish were released. VINO trap efficiencies using naturally produced salmon ranged from 7.5% to 24.2%, averaging 15.1% (n = 7). Trap efficiencies using MRFI salmon ranged from 0.9% to 11.7% and averaged 3.0% (n = 6). At flows ranging between 300-400 cfs, trap efficiencies using wild salmon as test fish were significantly higher than trap efficiencies using MRFI salmon as test fish (t-test: $t = -3.845$; $df = 11$; $P = 0.0027$). In addition, two paired tests took place, comparing trap efficiency rates using hatchery and naturally produced salmon. In both cases, efficiency rates were higher using naturally produced salmon (Table 1). Because of these significant findings, many efficiency tests using MRFI salmon were not used to generate salmon abundance estimates when tests using naturally produced fish were available (Table 1).

Eight calibration tests were conducted at the GOLF RST during the 2009/10 season (Table 1). All efficiency tests were conducted using MRFI salmon because only a small number of naturally produced salmon were available. Trap efficiency tests #2 and #6 were not used because the trap was stopped by debris shortly after the test fish were released. The failed calibrations were replaced using the following prediction formula:

$$\text{Log}(\text{TE}^{\text{R}}) = -0.87533 + -0.00828 * (\text{Mean FL}) + -0.00020 * (\text{Mean flow})$$

Where,

TE^{R} = Trap efficiency test replacement value

Mean FL = Mean fork length of chinook salmon caught at GOLF during the replacement time period.

Mean Flow = Mean flow at GOLF during the replacement time period.

This equation was derived using long-term efficiency data collected at the GOLF trap from 2005-2010. Average daily flow at release and mean FL of MRFI test salmon were used as the model effects (Logistic regression: $F = 20.8874$; $df = 2, 56$; $P < 0.0001$). The model explained 44% of the variation in the long-term efficiency data at GOLF. Using the prediction formula, efficiency rates for tests #2 and #6 were estimated to be 5.8% and 1.3%, respectively. Excluding the estimated values used for tests #2 and #6, GOLF trap efficiencies ranged from 0.3% to 4.4%, averaging 1.9% ($n = 6$).

Chinook Salmon

Catch and Abundance Estimates

During rotary screw trap monitoring, 8,401 naturally produced juvenile chinook salmon were captured at the VINO RST. Estimates for weekend catch were added to actual catch to produce a count of 16,610. Using trap efficiency data, the total estimated abundance of salmon passing the upstream RST (VINO) was 124,279 (CI: 93,555-199,950). The first and last salmon were caught on 18 December 2009 and 2 July 2010, respectively. The largest estimated number of salmon passed the VINO trap in January (Table 2).

At the GOLF RST, 441 naturally produced juvenile chinook salmon were captured between 5 January and 8 July 2010. Estimated weekend catch was added to the actual catch to produce a total count of 665. Using trap efficiency data, estimated salmon abundance at the downstream RST (GOLF) was 66,751 (CI: 38,914-283,316). The BYPASS trap captured 397 naturally produced juvenile chinook salmon between 16 April and 13 July 2010. Estimates for weekend catch were added to actual catch to produce an estimated count of 598. The total downstream emigration estimate, calculated from adding the BYPASS trap and the GOLF RST estimates, was 67,349 (95% CI: 39,512-283,914). At the downstream traps, the highest monthly abundance estimate was recorded in May (Table 2).

Life stage, size and condition

At the VINO RST, 84.6% of the salmon catch was classified as fry. Salmon fry fork lengths ranged from 27 to 40 mm and averaged 35 ± 2 mm ($n = 1,847$). The remaining catch was composed of 2.6% parr (FL ave. = 55 ± 9 mm, FL range = 38-77 mm, $n = 54$), 6.0% silvery parr (FL ave. = 66 ± 12 mm, FL range = 45-134 mm, $n = 132$), and 6.8% smolt (FL ave. = 90 ± 9 mm, FL range = 64-119 mm, $n = 140$). With the exception of two yearlings, all of the salmon caught at VINO were young of the year (age 0+) (Figure 3).

Chinook salmon catch at the downstream traps (GOLF and BYPASS) was dominated by smolt (90.7%). Smolt fork lengths ranged from 72 to 136 mm and averaged 97 ± 8 mm ($n = 735$). Other salmon catch included; 6.3% fry (FL ave. = 34 ± 2 , FL range = 29-37 mm, $n = 47$), 0.2% parr (no FLs taken), and 2.8% silvery parr (FL ave. = 79 ± 11 mm, FL range = 54-93 mm, $n = 22$). With the exception of one yearling, all of the salmon caught at the downstream traps were age 0+ (Figure 3).

The monthly average condition factor of all salmon life stages caught in the upstream and downstream traps is presented in Figure 4.

Migration Response

The relationships between three environmental variables (average daily flow, water temperature and turbidity) and estimated daily salmon passage at the upstream and downstream traps are presented in Figures 5 and 6. Linear regression analyses showed that each environmental variable had a significant linear relationship with salmon passage at the upstream trap; however they explained little of the variation in outmigration (Table 3). At the downstream traps, each environmental variable also had a significant relationship with salmon passage, but only explained some of the variation in outmigration (Table 3). Average daily releases from Camanche Dam explained the largest amount of variation (20%) in daily salmon passage estimates at the downstream traps (Linear regression: $F = 53.5197$; $df = 1, 211$; $P < 0.0001$).

Coded Wire Tagging

Naturally produced chinook salmon were coded wire tagged (CWT) at the VINO trap from 6 January to 12 May 2010. One tag code (06-09-02-01-02) was used to successfully tag 685 salmon captured at the VINO RST. Another 14 salmon did not survive the tagging process. Fork lengths of tagged salmon ranged from 37 to 134 mm and averaged 58 ± 20 mm ($n = 400$). All successfully tagged salmon (685) were released just below the VINO RST.

A different tag code (06-09-02-01-03) was used to tag 414 chinook salmon at the downstream traps (GOLF and BYPASS). The salmon were tagged from 16 April to 15 July 2010. Mean FL was 96 ± 7 mm ($n = 414$). Fish ranged in size from 76 to 116 mm. All salmon survived the tagging process and were released below the GOLF RST.

Six (1%) of the 685 chinook salmon coded wire tagged at the VINO FARMS were recaptured at the downstream traps (BYPASS and GOLF). One of the CWT salmon was recaptured at the GOLF trap, and the other five were recaptured at the BYPASS trap. Due to the low number of recaptures, a downstream abundance estimate for CWT salmon was not calculated.

A summary of coded-wire tagging efforts of naturally produced salmon since 1990 and corresponding recovery data is provided by Table 4.

Steelhead

Catch and Abundance Estimates

The first wild (natural production) age 0+ (<120 mm) steelhead was captured at the VINO RST on 25 February 2010. A total of 24 wild age 0+ steelhead was caught between 25 February and 2 July 2010. Estimated passage of wild age 0+ steelhead (based on salmon trap calibrations) was 745 (95% CI: 507-1,406). Steelhead catch also consisted of 4 wild age 1+ (\geq 120 mm) individuals and 26 hatchery origin (adipose fin clipped) yearlings (age 1+). The largest number of hatchery steelhead (16) was caught at VINO in March. The largest number of wild steelhead (10) was caught at VINO in April.

At the GOLF RST, 35 age 0+ (<120 mm) steelhead were captured between 22 April and 14 July 2010. Estimated passage of wild age 0+ steelhead at the GOLF trap (based on salmon trap calibrations) was 6,955 (95% CI: 4,344 - 20,897). Steelhead catch also consisted of 697 hatchery origin yearlings and 11 wild age 1+ (\geq 120 mm) individuals. At the BYPASS trap, 90 age 0+ (<120 mm) steelhead were captured between 20 April and 16 July 2010. Estimates of catch for non-trapping days were added to the count producing an estimate of 149 age 0+ steelhead. In addition, 6 wild age 1+ steelhead and 81 hatchery origin yearlings were caught at the BYPASS trap.

Combining the GOLF and BYPASS estimates, the total downstream passage of wild age 0+ steelhead was 7,144 (95% CI: 4,344 - 20,897). The largest number of hatchery steelhead (430) was caught at the downstream traps in March. The largest number of wild steelhead (66) was caught at the downstream traps in May.

Life stage and size

At the VINO RST, 75.0% of the naturally produced steelhead catch was classified as parr. The remaining catch was composed of 17.9% fry and 7.1% silvery parr. Naturally produced steelhead catch at the downstream traps (GOLF and BYPASS) was dominated by parr (83.5%). Other wild steelhead catch included 0.7% fry, 7.9% silvery parr, and 7.9% smolt.

Size and life stage data of wild steelhead caught at the upstream and downstream traps are presented in Figure 7.

Species Composition

At least 19 fish species were caught at the VINO RST during the survey period, 7 native and 12 non-native. Native fish species were more frequently caught than non-native species, comprising 99.5% of the total catch. Chinook salmon were the most abundant species caught (79.8%), followed by pacific lamprey (*Lampetra tridentata*) (18.4%) and prickly sculpin (*Cottus asper*) (0.6%).

At the downstream traps (GOLF and BYPASS) 28 fish species were caught, 8 native and 20 non-native. Native fish species were more frequently caught than non-native species,

comprising 96.7% of the total catch. Prickly sculpin were the most abundant species caught (69.6%), followed by pacific lamprey (12.4%), steelhead (wild and hatchery origin) (7.0%) and chinook salmon (6.4%).

DISCUSSION

At the upstream RST (VINO), frequent trap stoppages occurred towards the end of the season due to large changes in flow brought on by several cold storms. However, by this time over 90% of chinook salmon had passed the upstream trap, suggesting that the upstream passage estimate was minimally affected by the stoppages. Also, during this time, efforts were made to check the RST twice daily, thereby preventing additional stoppages. Conversely, many of the trap stoppages at the downstream RST (GOLF) occurred prior to the peak of chinook salmon emigration when less than 5% of the salmon had passed the downstream traps. The trap stoppages coincided with the filling of Lodi Lake, when large amounts of debris were washed past WIDD. Again, efforts were made to check the trap twice daily to prevent any additional stoppages.

The abundant catch of chinook salmon at the VINO RST allowed a large number of efficiency tests to take place during the beginning of the monitoring season. The significant difference in efficiency rates between hatchery and wild age 0+ salmon suggests that hatchery salmon may not be an acceptable surrogate for naturally produced salmon at the upstream RST. Roper and Scarnecchia (1996) also reported significantly higher trap efficiencies when using wild salmon (age 0+) as test fish. However, their result was obtained only when the trap was spinning slowly (2.4 RPM). Additional tests should be conducted in the future to determine if the same results are found under a variety of conditions. For example, almost all of the 2009/10 efficiency tests were conducted under similar flow conditions using age 0+ salmon fry (~ 40 mm). Nonetheless, when a sufficient number of naturally produced salmon are available for calibration tests at the VINO RST, they will likely provide an improved estimate of trap efficiency.

Only a small number of chinook salmon were caught at the GOLF RST and the BYPASS trap this season, preventing the use of naturally produced salmon as test fish for the efficiency trials at GOLF. Since the RST began fishing at GOLF in 2005, only five efficiency tests have been conducted using naturally produced salmon as test fish (EBMUD unpublished data). Three of the trials have yielded zero recaptures. In the future, the BYPASS trap may provide a large number of wild salmon to use as test fish.

Currently, our efficiency modeling efforts at GOLF rely on calibration tests using hatchery salmon as test fish. The logistic regression analysis established that GOLF trap efficiencies (2005-2010) were significantly related to the variables flow and average fork length and explained 44% of the variation in the data. Other Central Valley streams have established similar relationships between trap efficiency and the variables flow and fork length (Watry et al. 2008). Additional trap efficiency data under a larger range of flows may provide an improved model fit in the future. Although, if efficiency tests using wild salmon yield a significantly different result than efficiency tests using hatchery salmon,

the modeling process will need to alternately rely on efficiency trials using wild salmon as test fish.

The chinook salmon passage estimate of 124,279 at the VINO RST was lower than the 2007/08 and 2008/09 estimates of 1,117,451 and 175,612, respectively (Pagliughi et al. 2008; Boyd 2009). The number of salmon redds found during the 2007, 2008, and 2009 spawning seasons was 306, 63, and 248, respectively, providing no clues as to the cause of the decline (Pagliughi 2007; Del Real and Ribble 2008; Bilski and Ribble 2009).

However, several other factors may explain the unexpectedly low upstream passage estimate this season; trap efficiency data and/or predation by hatchery steelhead. This season the trap efficiency trials used to produce the abundance estimate at VINO were mostly trials using wild salmon as test fish. During the previous two seasons, only trials using hatchery salmon were applied (Pagliughi et al. 2008; Boyd 2009). Trap efficiency rates using hatchery fish were significantly lower than tests using wild salmon and may overestimate salmon abundance when applied to salmon catch.

In addition, a large in-river release of 163,093 age 1+ MRFI steelhead took place from 10 February to 19 February 2010 at Rkm 103, just below Camanche Dam (EBMUD unpublished data). This time period coincided with the peak of chinook salmon fry emergence according to the lower Mokelumne River egg model developed by Vogel (1993) (Figure 8). There also appeared to be a corresponding drop in chinook salmon passage at the VINO trap shortly after the release. A similar event occurred on the Feather River in 2002, when a large in-river release of hatchery steelhead (500,000) may have resulted in an unexpectedly low passage estimate at a nearby rotary screw trap (Kindopp and Gonzales 2007). During this monitoring effort, angling surveys were conducted concurrent with the peak of chinook salmon emigration and an average of 1.38 (± 3.98 SD) salmon fry were found in the stomachs of residualized hatchery steelhead ($n = 101$). While in-river releases of MRFI steelhead are important to help prevent straying, future release sites and release timing should be evaluated to consider the potential impacts of MRFI steelhead predation and competition on emerging and rearing wild chinook salmon.

The downstream chinook salmon passage estimate of 67,349 indicated that chinook salmon survival was high between the upstream and downstream rotary screw traps, given the upstream abundance estimate of 124,279. Last season, CWT recapture data also suggested that survival may be high between the upstream and downstream RSTs (Boyd 2009). However, it is important to note that the downstream abundance estimate relied on hatchery salmon as calibration fish, which may overestimate salmon abundance. In the future, mark/recapture studies using CWTs and/or VIE may be used to further investigate survival trends between the upstream and downstream trapping sites on the LMR.

During the 2009/10 trapping season, as well as previous two trapping seasons, environmental variables such as flow, water temperature, and turbidity have explained little of the variation in the estimated daily abundance of chinook salmon caught at the VINO RST (Pagliughi et al. 2008; Boyd 2009). On the lower Feather River, adult spawn

timing had a significant relationship with rotary screw trap catch at the upstream RST, positioned just below where the majority of chinook salmon spawn (Seesholtz et al. 2004). The same relationship may exist on the LMR at the VINO RST. In the future, adult spawn timing should be examined as an additional explanatory variable for the estimated daily abundance of chinook salmon caught at the upstream RST.

Water releases from Camanche Dam (flow) explained 20% of the variation in estimated daily abundance of chinook salmon at the downstream traps, and there was a significant linear relationship between the two variables. The ascending and descending limbs of the first spring pulse (mid-April) appeared to have the largest effect on salmon emigration. The following two pulses did not appear to influence salmon emigration. However, this may have been due to the fact that most of the salmon had already moved past WIDD during the first pulse.

Sixteen years of CWT recovery data from naturally produced salmon on the LMR indicate that the likelihood of an adult recovery is low. From 1990-2006, CWT recovery data (ignoring expansion factors) demonstrate that it takes an average of 1,286 naturally produced CWTd juvenile salmon from the LMR to obtain one adult recovery record. Unless more than 15,000 naturally produced LMR salmon can be CWTd each year, formal analysis of the data will be limited (as demonstrated by recovery data from 1999-2006). Future coded-wire-tagging efforts may be better suited towards gaining a better understanding of in-river survival of outmigrating juvenile salmon on the LMR.

ACKNOWLEDGEMENTS

We would like to thank Casey Del Real, Steve Boyd, and Jose Setka for their assistance, review, and field support. Thanks to Woodbridge Irrigation District for help with access and improvements at the downstream trapping sites. We would also like to thank all EBMUD Fisheries and Wildlife Division staff for their assistance on the project as needed.

Appendix B. Daily trap catch, trap efficiency, abundance estimates, and 95% confidence intervals (CI) of emigrating juvenile chinook salmon at the downstream traps (GOLF and BYPASS) on the lower Mokelumne River during the 2009/10 monitoring period. Shaded areas represent non-trapping periods.
